## Abstract

- 1        1) Undersampling can lead to missing trophic interactions in recorded food webs, with  
2        potential consequences for the perceived functioning and stability of the food webs.  
3        Undersampling can be compensated for by using food web models such as the allometric  
4        diet breadth model (ADBM) to predict missing links. Simultaneously, models might  
5        predict links which cannot occur, i.e., false positives.  
6        2) Previous research shows that (i) food web robustness (the inverse of the number of  
7        secondary extinctions occurring due to primary extinctions) increases with connectance  
8        (the number of realised trophic links divided by the number of possible links), and (ii)  
9        that predicted food webs usually have greater connectance than observed ones. Thus we  
10       expect that predicted food webs are more robust than observed ones. This expectation  
11       has never, to our knowledge, been tested, nor has the effect size been quantified.

---

- 3) We fill this research gap by comparing the robustness of observed food webs to the robustness of food webs predicted by a model (the ADBM) that can account for missing links, though can also make false positives. We did this for 12 different food webs from a wide variety of ecosystems.
- 4) We found, as expected, that the predicted food webs were more robust than the observed food webs, and this can be attributed to the higher connectance of the predicted food webs. On average, for every one unit of increase in connectance, we found the food webs to be robust by 0.52 units and 0.04 units for the most connected and the random species extinction scenarios respectively while no effect in the least connected species extinction scenario.
- 5) These results show that undersampling can lead to large underestimates of food web robustness that can be compensated for by filling in missing links with food web models. Nevertheless, increased connectance may contribute to lower dynamical stability, and so it would be interesting to compare the dynamical stability of observed and predicted food webs, as well as the topological stability that we have focused on.

## 1 Introduction

Anthropogenic changes such as climate change and habitat destruction are a threat to biodiversity, and can lead to food web collapse (Ullah et al. 2018). This food web collapse is due to the cascades of secondary extinctions in a food web because of the primary loss of species, for example due to habitat destruction and climate change (Pimm et al. 2006; J. A. Thomas et al. 2004; C. D. Thomas et al. 2004). Therefore, research focused on cascading secondary extinctions also known as ‘community viability analysis’ have been performed extensively in the past few decades to quantify how robust are food webs to species extinction (Jennifer A. Dunne, Williams, and Martinez 2002b; Jennifer A. Dunne and Williams 2009; Berg et al. 2011; Ebenman, Law, and Borrvall 2004; Ebenman and Jonsson 2005). And it has been shown that the rate of collapse of a food web is dependent on its structure and complexity (Jennifer A. Dunne, Williams, and Martinez 2002b; Jennifer A. Dunne and Williams 2009).

Simulation of primary species loss has been conducted in observed food webs and model food webs from terrestrial and aquatic ecosystems where robustness was measured in terms of secondary extinctions (Jennifer A. Dunne, Williams, and Martinez 2002b; Jennifer A. Dunne and Williams 2009). These studies have shown that the robustness of the food webs increases with food web connectance. Also, the removal of the most connected species cause considerably more secondary extinctions than the random removals of species (Jennifer A. Dunne, Williams, and Martinez 2002a; Sol’e and Montoya 2001). Simulation studies like

these which investigate the impact of primary extinctions in a food web to quantify robustness based on its topological structure provide an alternate solution to canonical experiments in natural ecosystems which are not possible or very difficult to conduct (Jennifer A. Dunne and Williams 2009).

Along with quantifying food web robustness based on its topological structure, studies such as Williams (2008), Brose, Williams, and Martinez (2006) and Martinez, Williams, and Dunne (2006) have quantified robustness based on the abundance dynamics of a food web. The topological approach of quantifying a food web robustness only requires the food web structure whereas the dynamical approach not only requires the food web structure but also the temporal dynamics of abundance of species in that food web. For example: Williams (2008) combined models of network structure with models of bioenergetic dynamics to study the role of food web topology and nonlinear dynamics on species coexistence in complex ecological networks.

A key assumption of the observed food webs is that they are very well sampled i.e. all the links that in reality can occur are represented. However, it is known that not all food webs are very well sampled and then do not represent all of the feeding links that occur (Caron et al. 2022; Patonai and Jord'an 2017; Jordano 2016). Some rare trophic links require more sampling effort as compared to others whereas some trophic links remain unobserved because of linkage constraints irrespective of sufficient sampling effort (Jordano 2016). Previous studies such as Caron et al. (2022) and Gupta, Furrer, and Petchey (2022) have shown that the predicted food webs from these models usually have greater connectance than the observed ones. Therefore, one solution to compensate for undersampling is to use a food web model such as the Allometric Diet Breadth Model (ADBM) to predict the missing links, and to then measure the robustness of the predicted food web. ADBM is a mechanistic model constructed using foraging rules based on the body sizes of prey and predator where trophic interactions satisfying those rules would be predicted by the model which are perhaps not observed because those interactions are rare. However, this solution is not infallible, as it is likely that the food web model might still miss some links, and also may predict some links that could not, in fact occur.

In our study, we investigate the topological robustness of the ADBM predicted food webs and compare it to that of the observed food webs, and quantify the effect of undersampling i.e overestimation of connectance on the robustness of these predicted food webs. We expect that the ADBM predicted food webs to be more robust as compared to the observed food webs, and for the greater robustness to be related to the amount by which the ADBM overestimates connectance. We do this by simulating primary species loss in 12 food webs predicted from the ADBM to quantify the secondary loss of extinctions. We use three different approaches of species removal: (i) most connected species, (ii) random species and (iii) least connected species to understand if the outcome varies among these approaches.

## 2 Materials and methods

In the upcoming sections, we present a detailed account of the implementation of simulation of primary extinctions for three different extinction scenarios on 12 food webs predicted by the ADBM from a wide variety of ecosystems and compute the resultant secondary extinctions. We then compute a robustness metric to quantify the robustness of those predicted food webs and compare them against that of the observed food webs.

### 2.1 Allometric Diet Breadth Model (ADBM)

The allometric diet breadth model (ADBM) is based on optimal foraging theory, specifically the contingency model (MacArthur and Pianka 1966). We chose this model because the ADBM can likely predict missing links in the predicted food webs because it consistently overestimated connectance in the predicted food webs as shown by our study in Gupta, Furrer, and Petchey (2022). The ADBM predicts the set of prey species a consumer should feed upon to maximise its rate of energy intake (Petchey et al. 2008). The foraging variables used in the model are the energy content of prey, handling times of the predator on prey, space clearance rate i.e. how fast a predator searches space, and prey densities. All of these variables are derived from the allometric scaling relationship using the body sizes of species. More details on the foraging rules defined in the ADBM and ADBM’s predictive power across different food webs can be found in Petchey et al. (2008).

### 2.2 Food web data

The observed food webs that we fit the ADBM to belong to marine, freshwater and terrestrial ecosystems (Table 1). These food webs contain primary producers, herbivores, carnivores, parasites, and parasitoids and also contain various types of feeding interactions, including predation, herbivory, bacterivory, parasitism and pathogenic. The observed connectance of these food webs varies from 0.03 to 0.24 and the number of species varies from 29 to 239 species.

The goodness of fit of the ADBM’s predictions depends on the interaction types in the food webs with predictions that are more size-structured such as aquatic and herbivory interactions being better predicted when compared to less size-structured ones such as parasitoid and terrestrial herbivory ones (Petchey et al. 2008).

Table 1: Information about the food webs predicted using the ADBM.

Common food web name (Original Publication)	Predation matrix source	General ecosystem	Number of species	Observed connectance	95% prediction interval of predicted connectance (Gupta et al. 2022)
Benguela Pelagic (Yodzis 1998)	Brose et al. (2005)	Marine	30	0.21	0.26 - 0.59
Broadstone Stream (taxonomic aggregation) (Woodward and Hildrew 2001; Woodward et al. 2005)	Brose et al. (2005)	Freshwater	29	0.19	0.18 - 0.72
Broom (Mommott et al. 2000)	Brose et al. (2005)	Terrestrial	60	0.03	0.12 - 0.89
Capinteria (Lafferty et al. 2006)	Hechinger et al. (2011)	Marine (Salt Marsh)	88	0.08	0.11 - 0.80
Caricaie Lakes (Cattin et al. 2004)	Brose et al. (2005)	Freshwater	158	0.05	0.11 - 0.81
Grasslands (Dawah et al. 1995)	Brose et al. (2005)	Terrestrial	65	0.03	0.03 - 0.44
Mill Stream (Ledger, Edwards, Woodward unpublished)	Brose et al. (2005)	Freshwater	80	0.06	0.08 - 0.60
Skipwith Pond (Warren 1989)	Brose et al. (2005)	Freshwater	71	0.07	0.17 - 0.90
Small Reef (Opitz 1996 Table 8.6.2)	Alyssa R. Cirtwill and Anna Eklöf (2018)	Marine (Reef)	239	0.06	0.07 - 0.66
Tuesday Lake (Jonsson et al. 2005)	Brose et al. (2005)	Freshwater	73	0.08	0.09 - 0.57
Ythan (Emmerson and Raffaelli 2004)	Alyssa R. Cirtwill and Anna Eklöf (2018)	Marine (Estuarine)	85	0.04	0.13 - 0.84
Broadstone Stream (size aggregation) (Woodward et al. 2010)	Guy Woodward. (2021)	Freshwater	29	0.24	0.25 - 0.47

### 2.3 Model parameterisation using approximate Bayesian computation

The ADBM was parameterised using approximate Bayesian computation (ABC) where a set of parameter values were sampled from the prior distributions. That set of parameter values was either accepted or rejected based on how close the predicted food web is to the observed food web using an accuracy metric – true skill statistic (TSS). The accepted parameter values then formed a posterior distribution. Further, prediction intervals of the true skill statistic and connectance of the predicted food webs were computed. In our study, we considered food webs where the predicted connectance lay within the 95% prediction interval. A detailed explanation of the parameterisation method can be found in Gupta, Furrer, and Petchey (2022).

### 2.4 Extinction scenarios and robustness

We implemented the primary species removal method from Jennifer A. Dunne and Williams (2009) by sequentially removing species using one of the three criteria: removal of (i) the most-connected species, (ii) the least-connected species and (iii) randomly chosen species. The most-connected and least-connected criteria are based on the degree (i.e. the total number of links to resources and from consumers) of species. We considered these mentioned criteria because the random extinction scenario takes into account all the theoretically possible extinction sequences of species that can occur in a food web and the extinction of most-connected species and least-connected species takes into account the two opposite extreme scenarios. These extinction scenarios have been widely used in studying species extinctions and collapse of food webs and other networks (Jennifer A. Dunne, Williams, and Martinez 2002b; Sol'e and Montoya 2001; J. Dunne, Williams, and Martinez 2004; Jennifer A. Dunne and Williams 2009; Albert and Barab'asi 2002).

Given a primary removal of species in a food web if any remaining species lost all of their resource species, or any cannibalistic species lost all of their resource species except the cannibalistic links, they are removed from the web and a secondary extinction was recorded. Secondary extinctions may cause further secondary extinctions, which were also checked for and recorded. Once no more secondary extinctions occurred, then another primary extinction was made, of the next appropriate species depending on the extinction scenario. This process was carried out until all the species were extinct from the food web.

130 The robustness ( $R$ ) of a food web was defined as the proportion of species subjected to primary  
 131 removals that resulted in a set of extinction (i.e. primary removals plus secondary extinctions) of  
 132 some specified proportion of the species. In our study, we use  $R_{50}$ , the number of primary extinctions  
 133 divided by the total number of species, which results in at least 50% of total species loss (Jennifer A.  
 134 Dunne, Williams, and Martinez 2002b; J. Dunne, Williams, and Martinez 2004; Jonsson et al. 2015;  
 135 Jennifer A. Dunne and Williams 2009). Therefore, if primary extinctions never cause any secondary  
 136 extinctions, the food web is maximally robust and ( $R_{50} = 0.50$ ). Whereas in a minimally robust  
 137 community ( $R_{50} = 1/S$ ), the first primary extinction causes a cascade of secondary extinctions of at  
 138 least nearly half of the species in the food web (i.e. at least  $S/2 - 1$ ).

## 139 2.5 Simulating species extinctions

140 First, we simulated primary species loss in food webs predicted by the ADBM which had the  
 141 maximum true skill statistics and compared it to primary species loss in observed food webs. Second,  
 142 to take into account the uncertainty in robustness in the ADBM predicted food webs we simulated  
 143 primary species loss and thereby computed robustness for all the ADBM predicted food webs  
 144 corresponding to the 95% prediction interval of the predicted connectance. In the case of the random  
 145 extinction scenario, we simulated 1000 random extinction sequences in a single ADBM predicted  
 146 food web.

## 147 2.6 Statistical analysis

148 In the random extinction scenario, we computed robustness  $R_{50}$  for all 1000 independent random  
 149 extinction sequences and calculated the median as a summary statistics to quantify the average  
 150 robustness of a single food web. To quantify the effect of undersampling i.e. overestimation of  
 151 connectance we compute the ratio of the difference in normalised robustness between the ADBM  
 152 predicted food webs and observed food webs to the difference in their normalised connectance, where  
 153 normalisation was performed by dividing the variables by their maximum possible values (I.e 0.5 for  
 154  $R_{50}$  and 1 for connectance). However, we did not perform any statistical significance test because  
 155 we work with simulated food webs and therefore the p-values of these tests are influenced by the  
 156 number of model simulations (White et al. 2014).

### 3 Results

We first present the secondary extinction curves of the ADBM predicted food webs which had the maximum true skill statistics and the observed food webs for 12 food webs under three different extinction scenarios. We then compare the robustness of all the ADBM predicted food webs within the 95% prediction interval against that of the observed food webs to take into account uncertainty in the robustness across food webs predictions. Finally we quantify the effect of overestimation of connectance on the difference in their robustness estimates.

#### 3.1 Secondary extinctions

In the most-connected extinction scenario, the cumulative secondary extinction curves started to rise steeply at a lower number of primary species removal in the observed food webs as compared to the ADBM predicted food webs for nine food webs (Fig. 1 (a, c, d, e, f, g, h, j, l)). However there were higher number of cumulative secondary extinctions occurring in the ADBM predicted food webs when compared to that of the observed food webs at a high number of primary species removal (Fig. 1 (a, f, g, h, k)). In the Skipwith Pond food web, there were no secondary extinctions for any number of primary removal of species (Fig. 1 (i)), whereas in the Broadstone Stream (taxonomic aggregation) food web the same was true only for the observed food web but in the ADBM predicted food web there was a steep rise in the cumulative secondary extinctions (Fig. 1 (b)).

In Fig. 2, we present the cumulative secondary extinctions in the ADBM predicted and the observed food webs for five (out of 1000) independent random extinction sequences to show qualitative differences between their secondary extinction curves. The secondary extinctions in the ADBM predicted food webs were more abrupt than that in the observed food webs.

Compared to the most-connected and random extinction scenarios, there were fewer secondary extinctions in the least-connected extinction scenario and therefore the secondary extinction curves were flat for most of the food webs (Fig. 3). In some of the food webs, the extinction curves of the ADBM predicted food webs overlapped with the observed food webs (Fig. 3 (b, c, g, h, i, k, l)). Contrary to the most-connected scenario, there was a very high number of secondary extinctions occurring at very low number of primary species removal (Fig. 3 (a, d, e, f, j)).

Figure 1: Cumulative secondary extinctions of species resulting from the primary **removals of the most connected species** in the ADBM predicted food webs corresponding to the maximum TSS and observed food webs.  $S$  denotes the number of species in a food web. The cumulative secondary extinctions of species and the number of species removed have been normalised by the number of species.

Figure 2: Cumulative secondary extinctions of species resulting from the primary **removals of random species** in the ADBM predicted food webs corresponding to the maximum TSS and observed food webs for five independent random extinction sequences.  $S$  denotes the number of species in a food web. The cumulative secondary extinctions of species and the number of species removed have been normalised by the number of species.

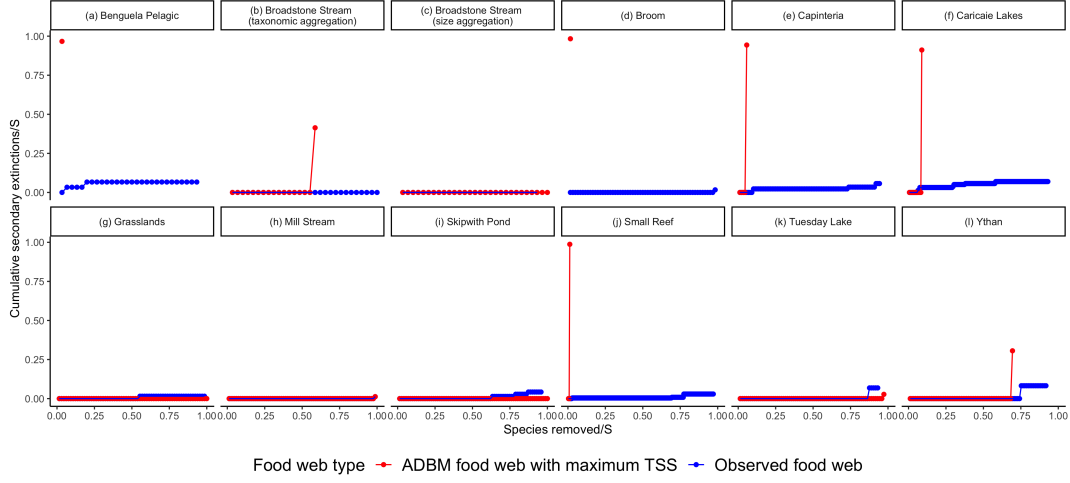

Figure 3: Cumulative secondary extinctions of species resulting from the primary **removals of the least connected species** in the ADBM predicted food webs corresponding to the maximum TSS and observed food webs.  $S$  denotes the number of species in a food web. The cumulative secondary extinctions of species and the number of species removed have been normalised by the number of species.

### 3.2 Robustness

The ADBM predicted food webs were more robust than the observed food webs on average in the most-connected and random extinction scenarios (Fig. 4 (a, b)). However, there were large variations in the robustness within the ADBM predicted food webs in the most-connected extinction scenario (Fig. 4 (a)). For example, the ADBM predicted Caricaie Lakes food web was more robust than the observed food web on average but had a larger variation in the robustness within the ADBM predicted food webs compared to other food webs.

The food webs were more robust to the random extinction scenario than the most-connected scenario (Fig. 4 (a, b)). Small Reef and Benguela Pelagic food webs had more variations in robustness within the ADBM predicted food webs as compared to the other food webs (Fig. 4 (b)). Skipwith Pond, Broadstone Stream (taxonomic aggregation) and Broadstone Stream (size aggregation) food webs were the most robust (Median  $R_{50} = 0.5$ ) for both ADBM predicted and observed food webs. Although there were few less robust ADBM predicted food webs in the Broadstone Stream (size aggregation) as shown by the outliers.

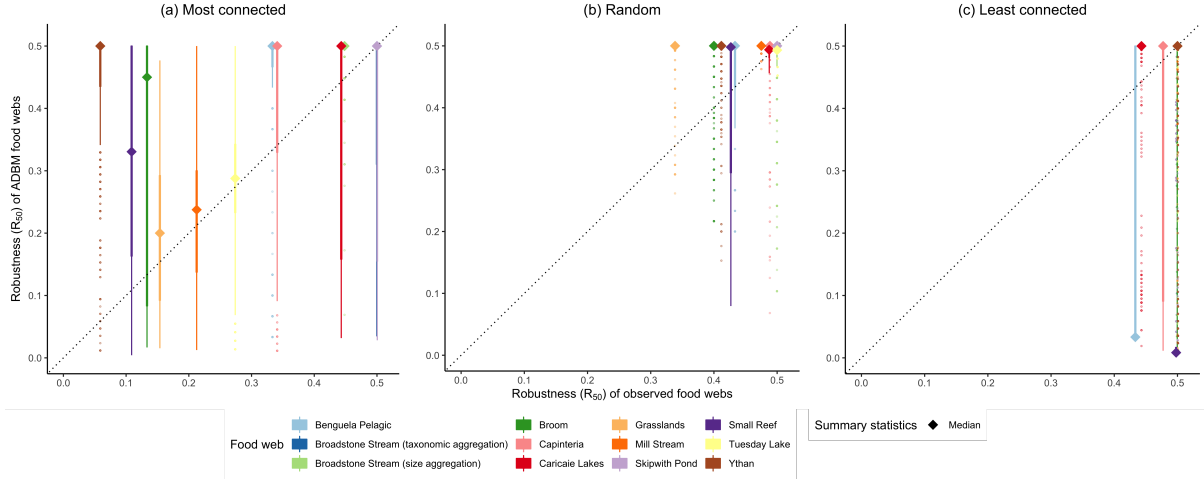

Figure 4: Robustness comparison between the ADBM predicted food webs and the observed food webs for 12 food webs across different ecosystems. Here,  $R_{50}$  is the proportion of species that have to be removed to achieve a total loss of at least 50% of total species (primary removals and secondary extinctions). Box represent 25th and 75th percentile; solid diamond represent median; whisker represent outlier limits; the outlier coefficient used was 1.5. Some points are not visible due to perfect overlap in b and c. Refer to Fig. 7 in the Supplementary Information for a faceted visualisation.

198 In the least-connected extinction scenario, the food webs had a very high robustness (Median  
 199  $R_{50} = 0.5$ ) for most of the food webs (Fig. 4 (c)), however there were some exceptions. The ADBM  
 200 predicted food webs for Small Reef and Benguela Pelagic had very low median robustness. Benguela  
 201 Pelagic, Broom and Capinteria food webs from the ADBM had larger variations in robustness when  
 202 compared to that of the others.

203 In all of the food webs except Small Reef and Broadstone Stream (taxonomic aggregation),  
 204 the effect size was positive on average in the most-connected extinction scenario (Fig. 5 (a))  
 205 i.e. overestimation of connectance had a positive effect on the robustness. In the random extinction  
 206 scenario, there was a positive effect of overestimation of connectance on the robustness for Ythan,  
 207 Small Reef, Mill Stream, Grasslands, Caricaie Lakes, Capinteria, Broom and Benguela Pelagic (Fig.  
 208 5 (b)). However, the effect size varied across the food webs. In the least-connected extinction  
 209 scenario, the overestimation of connectance had little effect on average on the difference in the  
 210 robustness (Fig. 5 (c)).

Figure 5: Effect size (i.e ratio of difference in normalised robustness between ADBM predicted food webs and observed food webs to difference in their normalised connectance) shown for the 12 food webs. Box represent 25th and 75th percentile; black bold midline represent median; whisker represent outlier limits; the outlier coefficient used was 1.5.

## 4 Discussion

The primary removal of species revealed that the ADBM predicted food webs are more robust than the observed food webs on average, with variation within the robustness of the ADBM predicted food webs in the 12 food web ecosystems suggesting that undersampling in food webs can lead to differences in the estimates of food web robustness. The food webs are least robust to primary extinction of the most connected species scenario compared to that of least connected and random extinction scenarios on average. A future development would be to understand how undersampling i.e. overestimation of connectance influences the stability of the dynamics of the ADBM predicted food webs against that of the observed food webs, and compare it with our study.

The robustness of the ADBM predicted food webs were higher than that of the observed food webs on average (Fig. 4) for all of the 12 food web ecosystems with some exceptions. This can be attributed to the higher connectance of the ADBM predicted food webs as compared to that of the observed food webs because a species in a food web with a higher connectance has on average more trophic links as compared to a food web with a lower connectance (Fig. 5). Our study suggests that it is important to consider undersampling in observed food webs when computing their robustness.

226 The findings from our study are similar to what had been documented for other food web  
 227 models (Jennifer A. Dunne and Williams 2009), in terms of an increase in the robustness when  
 228 the connectance of a food web is increased. However, contrary to general expectations (Jennifer  
 229 A. Dunne, Williams, and Martinez 2002a), food web robustness did not always increase with the  
 230 connectance (Fig. 5). The ADBM consistently predicted higher connectance than that of the  
 231 observed food webs however, in some cases an increase in connectance resulted in lower robustness  
 232 (Fig. 5) in the predicted food web. For example: the Benguela Pelagic and Small Reef food webs  
 233 were surprisingly less robust to primary extinctions on average in the least-connected extinction  
 234 scenario (Fig. 4 (c) and 5 (c)). We suspect this is because the ADBM is underestimating the  
 235 proportion of basal species in the predicted food webs when compared to that of the observed food  
 236 webs (Fig: 6 (a) in Gupta, Furrer, and Petchey (2022)). As a result, these low degree basal species  
 237 are the ones to be removed at an early stage in the deletion sequence thereby resulting in an earlier  
 238 food web collapse in the ADBM predicted food web as compared to that of the observed food web  
 239 (Fig: 3 (a) and (j)). This suggests that the overestimation of connectance by the ADBM resulted  
 240 in a more robust food web on average but differences in the predicted food web properties such  
 241 as underestimation of the proportion of basal species and overestimation of the maximum trophic  
 242 level (Fig: 6) counteracted that effect and led to reduced robustness. This suggests that food web  
 243 properties other than connectance play an important role in determining the robustness of a food  
 244 web and therefore should be also taken into account.

245 The ADBM based on its size-based rules predicts the diet of a consumer and hence is able  
 246 to predict some links in the predicted food webs which do in reality occur but are actually not  
 247 observed in the observed food webs perhaps because of low sampling effort. A future study could  
 248 be to extend our study to use other food webs models based on size-based rules such as Gravel et  
 249 al. (2013) and Vagnon et al. (2021) and compare them with our study. We expect similar results  
 250 because these food webs are also based on body size rules.

251 As with any food web model, we expect that there are real false positives in the food webs  
 252 predicted by the ADBM. Firstly this may be because the ADBM uses only body size as a trait. A  
 253 trait uncorrelated with the body size may be influential in determining the interaction between  
 254 two species (Gupta, Furrer, and Petchey 2022). Secondly, the ADBM can only predict diets that  
 255 are contiguous with respect to the size of the prey. I.e. it cannot predict that the consumer will

consume prey of size 1 and 3, and not consume prey of size 2. However, it is important to note that observed diets are not always contiguous when prey are ordered by their size due to some ecological differences in how predator species choose their prey (Caron et al. 2022). Therefore a future study could extend our study with other food web models which are not based on body size such as Cattin et al. (2004) and Allesina, Alonso, and Pascual (2008). We expect to have a difference in results based on whether the trophic interactions in the food webs are governed by size-structured rules or not.

It would be intriguing to know if this difference in connectance has a similar influence on the dynamical stability of the food webs as well. Hence, a prospect could be to use a dynamical model (for example bioenergetic food web model by Brose, Williams, and Martinez (2006)) to model the temporal dynamics of the ADBM predicted food webs. We expect that the difference in dynamical robustness of the ADBM predicted and the observed food webs would be similar to differences in their topological robustness because the dynamical robustness of the ADBM predicted and the observed food webs would be both underestimated when compared to their topological robustness (Curtisdotter et al. 2011).

Since the ADBM underestimates the proportion of basal species and overestimates the maximum trophic level in the predicted food webs compared to that of the observed food webs, it would be interesting to use these properties as summary statistics to parameterise the ADBM and investigate how that influences the difference in the robustness between the ADBM predicted and the observed food webs.

We have used a food web model to compensate for undersampling in recorded food webs and thereby quantified the influence of missing links i.e. overestimation of connectance on the topological robustness of 12 food webs from various ecosystems. We found that the overestimation of connectance can have large impacts on the robustness of the food webs with variation in robustness among the predicted food webs which have also been influenced by differences in the structural food web properties between the ADBM predicted food webs and the observed food webs.

 316 Webs.” *Marine Ecology Progress Series* 273: 291–302. <https://doi.org/10.3354/meps273291>.

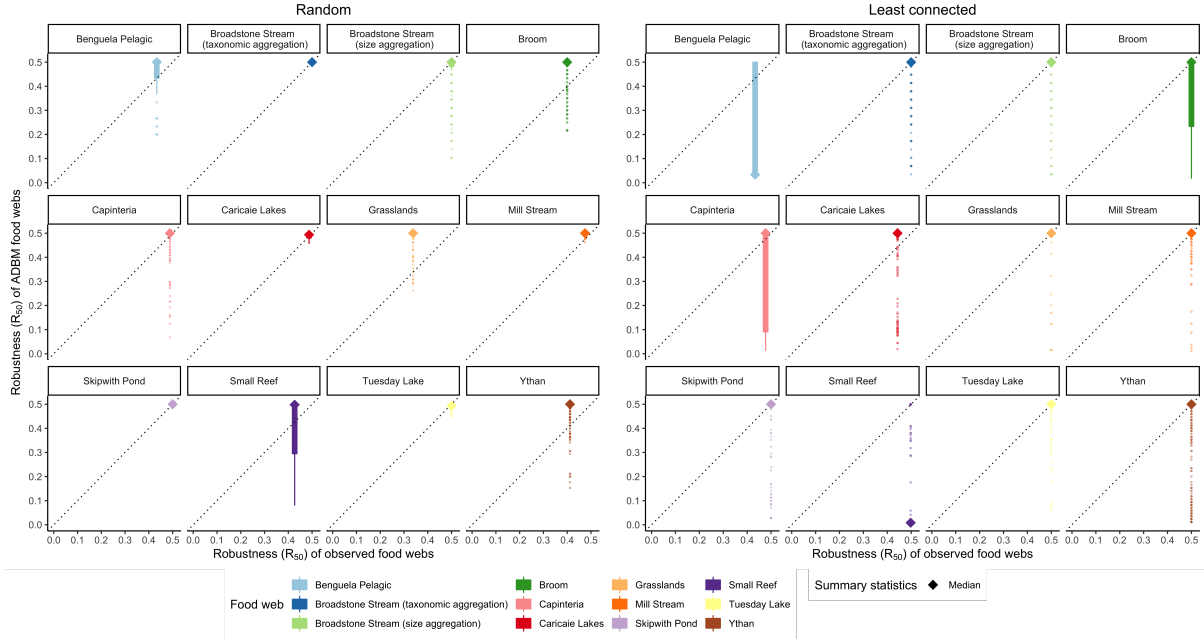

Figure 7: Robustness comparison between the ADBM predicted food webs and the observed food webs for 12 food webs across different ecosystems for random and least connected extinction scenarios. Here,  $R_{50}$  is the proportion of species that have to be removed to achieve a total loss of at least 50% of total species (primary removals and secondary extinctions). Box represent 25th and 75th percentile; solid diamond represent median; whisker represent outlier limits; the outlier coefficient used was 1.5.
